# 3 Comparison of Photochemical Mechanisms for Air Quality Modeling

Published as Jiménez, P., Baldasano, J.M., Dabdub, D., 2003. Comparison of photochemical mechanisms for air quality modeling. Atmospheric Environment, **37**, 4179-4194.

### 3.1 Introduction

One of the most important components of air quality models (AQMs) is the photochemical mechanism. A photochemical mechanism for tropospheric chemistry is a mathematical description of photochemical processes of the lower atmosphere through a series of chemical reactions involving primary and secondary pollutants. Photochemical mechanisms used in AQMs are not described in full detail because chemical reactions produce a large number of intermediate non-stable compounds, which disappear quickly and are difficult to detect because of a lack of adequate instrumentation. In addition, the large amount of potential species inhibits the creation of a fully described mechanism from a computational standpoint. Species considered in a photochemical mechanism are categorized as inorganic compounds (NO<sub>x</sub>, O<sub>x</sub>, HO<sub>x</sub>, and SO<sub>x</sub>) and organic compounds, mainly volatile organic compounds (VOCs).

The variety of VOCs emitted to the atmosphere is wide, and its spatial and temporal speciation in emission inventories is complex. Because of the lack of detailed information about VOCs in emission inventories, species in the chemical mechanism are not usually explicit, but lumped. The implementation of a mechanism into an AQM involves the solution of a highly coupled, nonlinear, system of stiff differential equations. The majority of the computing time for tropospheric gas-phase modeling (80-90%) is consumed integrating the chemistry of rate equations (Dennis *et al.*, 1996). Therefore, it is critical to avoid introducing unnecessary complexity into the photochemical mechanism. Divergence points among different chemical schemes are: (1) formulation of the reaction mechanism, (2) rate constants for the reactions and their temperature and pressure dependencies, and (3) temporal integration of the reaction rates by the chemical solver (Kuhn *et al.*, 1998).

In this work, the results of a comparison of seven photochemical models are presented. Table 3.1 lists the mechanism studied, their main characteristics and the air quality models where they are implemented (Russell and Dennis, 2000). Key species followed in this study are O<sub>3</sub>, NO, NO<sub>2</sub>, NO<sub>3</sub>, HNO<sub>3</sub>, peroxyacetyl nitrate (PAN), HO<sub>2</sub>, H<sub>2</sub>O<sub>2</sub> and two organic compounds: ethene and isoprene. The election of these species is based on other works (Gao *et al.*, 1996; Olson *et al.*, 1997; Kuhn *et al.*, 1998, Luecken *et al.*, 1999), and comprises the most important photooxidant species.

## 3.2 Previous Comparisons of Mechanisms

It is well known that different photochemical mechanisms produce dissimilar results. Some authors have compared several schemes throughout the past decade.

Jeffries and Tonnesen (1994) compared the CBM-IV and SAPRC90 using a Lagrangian model, with an analysis method that includes a mass budget to determine the origin of the differences between them. Both mechanisms are based in the same set of experiments of a photochemical smog chambers study. The most important discrepancies were found in high VOCs/NO<sub>x</sub> ratios, producing a smaller amount of O<sub>3</sub> with CBM-IV.

Poppe *et al.* (1996) compared twelve chemical mechanisms with numeric simulations in a box model. They used five scenarios, three of them without emissions, to determine the behavior of reactions in the farthest areas from emission sources; and two with emissions. Most mechanisms reported similar  $O_3$  levels. On the other hand, concentrations of peroxyacetyl nitrate (PAN),  $H_2O_2$  and  $NO_3$  depended much on the mechanism used. The difference in the prediction of concentrations of ozone among all photochemical mechanisms was of 30%.

Olson *et al.* (1997) presented the results from the Intergovernmental Panel on Climate Change (IPCC) tropospheric photochemical model intercomparison (PhotoComp). The authors used a five-day diurnal box model simulation to compare the mixing ratios of  $O_3$ ,  $O_4$ ,  $O_4$ ,  $O_5$ ,  $O_6$ ,  $O_8$ ,

With the inclusion of non-methane organic gases in the simulation,  $O_3$  and  $NO_x$  means and medians diverged by up to 25%. Models lacking the pressure and water vapor pathways of the  $HO_2$  self-reactions tended to predict lower  $H_2O_2$  mixing ratios in favor of increased  $HO_2$ . Differences in  $HO_2$ , in turn, were likely due to the inconsistent reaction rates used by the models for the self- $HO_2$  reaction to yield  $H_2O_2$ , and to differences in the model-calculated photolysis of  $H_2O_2$  and  $CH_2O_3$ .

Kuhn *et al.* (1998) compared nine chemical mechanisms. The pressure and water vapor pathways of the  $HO_2$  self-reaction were not included in all mechanisms. Significant differences in  $H_2O_2$  predictions were explained partly by an incorrect use of the  $HO_2$  self reaction rate constant and by differences in the treatment of the peroxy radical interactions. One of the main conclusions was that most chemical schemes examined yielded similar  $O_3$  concentrations, despite differences in the hydrocarbon lumping. The calculated concentrations of other longer-lived species like  $H_2O_2$  and PAN differed considerably (up to 73%). Also, some of the differences in schemes presented in the comparison reflected differences in numerical solution methods rather than differences in chemistry.

Luecken *et al.* (1999) examined the production and speciation of reactive oxidized nitrogen ( $NO_y$ ) from three mechanisms. The most important reaction in  $NO_y$  chemistry is the oxidation of isoprene, which influences the production of PAN and organic nitrate. Differences among mechanisms caused large differences in  $NO_y$  concentrations. Nitric acid production during the day was consistent among mechanisms. PAN concentration was determined by acylperoxy radicals ( $C_2O_3$ ) rates, meanwhile  $NO_3$  prediction for models varied over a large range.

Andersson-Skold and Simpson (1999) described the chemical comparison between the EMEP chemical scheme and a more comprehensive chemical mechanism, the IVL. Despite the divergences in the complexities of the models, predicted ozone levels from both chemical mechanisms were similar for different scenarios. Differences in ozone appeared because of the description of the organic chemistry; IVL treats the chemistry of each VOC in greater depth, including features as  $RONO_2$  formation and extensive  $RO_2 + RO_2$  chemistry, not included in EMEP. A major difference between the schemes was a higher formation of aldehydes in the IVL scheme, brought about mainly by OH + alkane reactions.

Tonnesen and Luecken (2000) compared SAPRC99 and CB-IV\_99 using a Lagrangian model, OZIPR. They found that both mechanisms produce similar predictions for ozone at conditions near the ridgeline of maximum O<sub>3</sub>. Nevertheless, CB-IV\_99 predicts higher O<sub>3</sub> levels for radical-limited conditions, and SAPRC99 predicts higher ozone concentrations for NO<sub>x</sub>-limited conditions. Furthermore, there was considerable temporal variability between the two mechanisms (ozone production is much more rapid in SAPRC99).

Dodge (2000) reviewed five chemical mechanisms used in air quality simulation models (the CBM-IV, the SAPRC mechanism, the RADM2 and RACM models and a new mechanism called the Morphecule Mechanism). The mechanisms yielded similar ozone predictions when exercised under clean tropospheric conditions as well as under conditions more representative of polluted boundary layer. Ozone predictions were found to agree within 10%. Nevertheless, concentrations of other oxidants such as  $H_2O_2$  differed considerably.

The novel approaches of this document are that comparison includes those chemical schemes as used by air quality models with the latest available parameterizations up to date. In addition, CACM mechanism has never been included previously in a comparison work. CACM is a mechanism with an increasing importance since it provides the right speciation of organics necessary for secondary aerosol production.

#### 3.3 Photochemical Mechanisms

A brief description of the mechanisms as implemented in the air quality models depicted in Table 3.1 is presented in this section, summarizing the main characteristics that should be underlined and highlighting their differences.

The LCC mechanism is presented in Lurmann  $et\ al.\ (1987)$ . Forty-eight of the species are treated as integrated species in the kinetic solver. Three of the species (M, O<sub>2</sub> and H<sub>2</sub>O) are treated as constants and fourteen of the species are treated as steady-state species. Aromatic reactions include a parameterized representation of the aromatic ring opening products. PAN analogues from non- $\alpha$ -dicarbonyl products are lumped with PAN analogues formed in other areas of the mechanism. Since the early LCC mechanism did not include biogenic species, the modified scheme used in the CIT Airshed Model comprising 169 reactions and 65 species (McRae  $et\ al.$ , 1992) includes biogenic organic compounds such as isoprene,  $\alpha$ -pinene,  $\beta$ -pinene, myrcene,  $\gamma$ -carene and limonene and their reactions with OH, O, NO<sub>3</sub> and ozone, and also revises the oxidation of organic compounds by the reaction with OH.

CBM-IV (Gery *et al.*, 1989) is a lumped-structure condensed mechanism. Carbon bond approach is utilized for the lumping of organic species. The mechanism contains 33 species represented in 81 reactions, and treats the reactions of four different types of species: inorganic species, explicit organic species, organic species represented by carbon surrogates, and organic species that are represented by molecular surrogates. Inorganic chemistry is represented explicitly with no lumping. Organics represented explicitly are formaldehyde, ethene and isoprene. Carbon bond surrogates describe the chemistry of different types of carbon bonds commonly found as parts of larger molecules. CBM-IV is widely used in research and regulatory air quality models as Models-3/CMAQ (Byun and Ching, 1999), and this will be the scheme implemented in this comparison.

RADM2 (Stockwell *et al.*, 1990) is built on the RADM1 scheme (Stockwell, 1986). It includes 156 reactions among 63 species. The most important upgrades include three classes of higher alkanes, a detailed treatment of aromatic chemistry, two higher alkene classes that represent internal and terminal alkenes, treatment of ketones and dicarbonyl species as classes distinct from aldehydes, inclusion of isoprene as an explicit species and a detailed treatment of peroxy radical-peroxy radical reactions. Inorganic species include 14 stable species, 4 reactive intermediates and three abundant stable species (oxygen, nitrogen and water). H<sub>2</sub> is not included in the mechanism. Atmospheric organic chemistry is represented by 26 stable species and 16 peroxy radicals. Volatile organic compounds are grouped together into a manageable set of VOCs classes based on similarity of oxidation reactivity and emission magnitudes (Middleton *et al.*, 1990). Organic compounds are aggregated into 15 classes of reactive organic species. The implementation of RADM2 in Models-3/CMAQ is analogous to that described by Stockwell *et al.* (1990) with only two minor modifications: the reaction of OH with cresol was reformulated to eliminate negative stoichiometry in the mechanism, and the concentration of methane is assumed to be constant (Gipson and Young, 1999).

EMEP (Simpson, 1992; Simpson *et al.*, 1993) is of particular importance to policy-related studies in Europe. It uses a lumped molecule approach to represent organic compounds. Each species in the EMEP mechanism represents a range of species of similar structure and reactivity. Photodissociation rates for 13 species are specified in the model as a function of the solar zenith angle. The EMEP version used is based on Simpson *et al.* (1993), but the isoprene mechanism has been updated, implementing some reactions proposed by Paulson and Seinfeld (1992). EMEP includes reactions of isoprene with OH, NO<sub>3</sub> and ozone. In addition, eight reactions and four species proposed by Simpson (1995) have been added to model the interactions between the peroxy radicals from the isoprene degradation and HO<sub>2</sub>. This updated mechanism includes 135 reactions and 64 species, and is used on the EMEP MSC-W air quality model (Simpson, 1992, 1995), developed to study formation and transport of ozone over long term periods in Europe.

RACM (Stockwell *et al.*, 1997) is a completely revised version of the RADM2. The mechanism includes 17 stable inorganic species, 4 inorganic intermediates, 32 stable organic species (4 of these are primarily of biogenic origin) and 24 organic intermediates, in 237 reactions. Changes in inorganic chemistry from previous RADM2 mechanism were relatively small. An accurate representation of the production of  $CO_2$  is excluded both from RADM2 and RACM mechanisms. In RACM, the volatile organic compounds are aggregated into 16 anthropogenic and 3 biogenic model species. The grouping of organic chemical species into the RACM model species is based on the magnitudes of the emission rates, similarities in functional groups and the compound's reactivity toward OH. The organic chemistry was revised significantly. The aromatic chemistry was more widely treated in RACM, including amounts of products from the aromatic-OH addition that had been ignored in RADM2. The oxidation mechanism for isoprene,  $\alpha$ -pinene, and d-

limonene is more detailed and realistic than that in the RADM2 mechanism. This scheme has been implemented in the EURAD air quality model (Hass, 1991).

The latest version of the SAPRC mechanism, designated SAPRC99 (Carter, 2000a) represents a complete update of the SAPRC90 mechanism by Carter (1990). The mechanism has assignments for 400 types of VOCs, and can be used to estimate reactivities for 550 VOC categories. The inorganic reactions in the mechanism are essentially the same as those included in previous versions. A total of 24 model species are used to represent the reactive organic product species: 11 are explicit, and 13 represent groups of similar products using the lumped molecule approach. The PAN analogue formed from glyoxal is lumped with the rest of the higher PAN analogues. Isoprene photooxidation products in the mechanism are included. SAPRC uses a condensed representation of the reactive organic oxidation products and a higher condensed representation of peroxy reactions than does RADM2 or RACM. The SAPRC99 mechanism used in Models-3/CMAQ consists of 72 species in 198 reactions, as described in Carter (2000b).

CACM, developed by Griffin *et al.* (2002), is the first detailed mechanism directed toward explicit formation of the semivolatile products that could constitute observed secondary organic aerosols (SOA), and has been implemented in the CIT airshed model. It includes a total of 191 species and 361 reactions: 120 fully integrated species (15 inorganic, 71 reactive organic and 34 unreactive organic), 67 pseudo-steady-state species (2 inorganic and 65 organic); and 4 fixed-concentration species. The inorganic chemistry within CACM is derived primarily from the SAPRC99. Primary organic compounds are lumped in a manner similar to that described by Stockwell *et al.* (1997). Oxidation reactions of surrogate parents are tracked individually. The lumped model compound corresponding to a given individual parent hydrocarbon is determined by considering the size of the molecule, its structural characteristics, its functionality, its reactivity, and its SOA forming potential. Isoprene is treated explicitly in the CACM, and methyl-vinyl-ketone and methacrolein are major oxidation products of isoprene and are included explicitly. For monoterpenes, CACM incorporates a class (BIOH) for those monoterpenes that have relatively high SOA yield parameters, and another class (BIOL) for those with a relatively low SOA-yield.

## 3.4 Methodology

The results presented here correspond to a scenario representing a remote troposphere simulation, since this is the simplest and straightforward case to analyze. This scenario starts from an initial set of trace gas concentrations without emissions, and is sensitive to the details of the formulation of organic species and the rate constants for the reactions in the individual schemes. In addition, this work is focused on elucidating the variability of results among published models, and therefore parameters were chosen to make all mechanisms absolutely comparable. The methods used are similar to those followed by Poppe *et al.* (2001). The photolysis rate coefficients are calculated for the longitude and latitude of the South Coast Air Basin of California.

Simulations account for diurnally dependence of photolysis rate coefficients. The base temperature is 298.16 K, remaining constant during the simulation. Calculations are started at 0 LST and cover the following 24 hours; all the same, results show the hours where solar radiation is present, from 6 LST until 18 LST, since photochemical processes are more active at this time of the day. The initial concentrations are derived from Gao *et al.* (1996) and Seefeld and Stockwell (1999). All depositions are set to zero in order to concentrate on differences in the chemical schemes. Table 3.2 shows other parameters of the scenarios modeled.

**Table 3.2.** Parameters specifications and initial conditions (ppm) for scenario.

$H_2O$	15,500						
Temperature: 298.16 K							
Pressure: 1013.25 mbar							

Simulations are performed using a zero-dimensional box model. The stiffness of the system of ordinary differential equations (ODE) requires the use a robust numerical integrator. The VODE library (Brown *et al.*, 1989), in its single precision version (SVODE), is chosen to perform the simulations. Gurciullo *et al.* (1998), reported that VODE is a factor of two faster than the second most efficient solver included in the comparison for the same tolerated accuracy.

Before summarizing the results, it is worth emphasizing that this works represents a comparison of models. It is impossible to know what "correct results" should be from any atmospheric chemical scheme. Comparison with smog-chamber data could be a useful complement; nevertheless, smog chambers also represent a very artificial system with many unknown influences. Because of all these reasons, the methodology used in this work proposes the comparison of models with an average tendency, and has been widely supported and applied in the literature (Olson et al., 1997; Kuhn et al., 1998; among others).

### 3.5 Results

# 3.5.1 Inorganic Chemistry of Nitrogen Oxides and Ozone

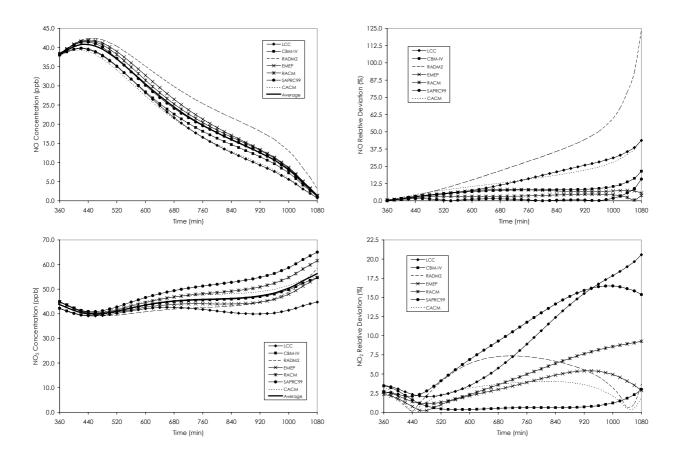

The kinetics of the gas-phase reactions of inorganic species in the troposphere are relatively well understood. For instance,  $O_x$ -H $O_x$ -N $O_x$  interactions are reflected in a similar way in all mechanisms studied here. Gas-phase inorganic reactions are described, reviewed and evaluated by DeMore *et al.* (2000) and Atkinson *et al.* (1999). However, there are a few reactions not fully understood that impact the ability to quantify the formation, cycling and losses of  $O_3$  and  $NO_x$  in the troposphere (Atkinson, 2000).

In general, predicted concentrations of  $NO_x$  for all models show only small differences (Figure 3.1). RADM2 has by far the highest NO concentrations, twice as much as the mean. On the other hand, LCC and CACM mechanisms underpredict NO, yielding 16% less NO than the average. SAPRC99's predictions for  $NO_2$  are 10% higher than the mean and lie on the top of the range. On the other side, LCC shows an averaged prediction of about 9% under the mean values. The explanation of this result is that LCC contains the fastest parameterizations for the transformation of  $NO_x$  to nitrate radical and nitric acid; as will be described later, LCC predicts the highest levels of  $HNO_3$ .

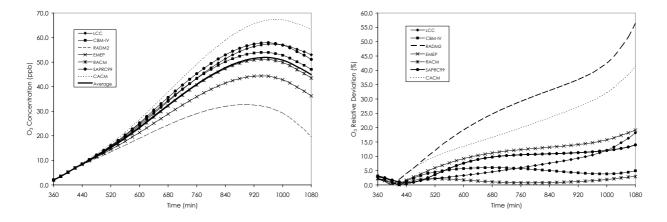

Another significant difference to report is that EMEP mechanism does not include the nitrous acid (HONO) reactions, and this species represents one of the main sources of hydroxyl radical and NO in the troposphere, since HONO is rapidly photolyzed at wavelengths under 400 nm during daytime hours (Finlayson-Pitts and Pitts, 2000).

Ozone concentrations are sensitive to NO and NO<sub>2</sub> and their reactions in the troposphere (Table 3.3), and also to the NO<sub>2</sub> photolysis rate and PAN formation and loss rates (Gao *et al.*, 1996).

The important reactions responsible for  $O_3$  destruction are directly related to OH and  $HO_2$  chemistry. Figure 3.2 shows ozone concentrations during high photochemical activity hours. CACM is the highest-yielding mechanism (values 19% over the average). CACM's predictions are twice as large as those produced by RADM2, which presents a 25% deviation below the average. The maximum deviation of all mechanisms for ozone formation is less than 20% for all simulations. The average deviation is between 1 and 10%. Results obtained show a relation between the dynamics of ozone and hydroperoxide radicals, since those pollutants are coupled through the reaction  $O_3 + HO_2 \rightarrow OH + 2O_2$ . Most of the model differences with respect to ozone concentrations are traced to differences in the destruction of  $O_3$  due to reaction with  $HO_2$ .

### 3.5.2 Nitrate Radical and Nitric Acid

The nitrate radical (NO<sub>3</sub>) is a strong oxidizing agent and reacts with a number of other atmospheric species. The prerequisite for NO<sub>3</sub> radical production is the simultaneous presence of NO<sub>2</sub> and O<sub>3</sub> in the same air mass. The reaction NO<sub>2</sub> + O<sub>3</sub>  $\rightarrow$  NO<sub>3</sub> + O<sub>2</sub> is the only primary source of NO<sub>3</sub> in the troposphere (Seinfeld and Pandis, 1998). During daytime, NO<sub>3</sub> rapidly photolyzes and reacts with NO to yield NO<sub>2</sub>. In addition, NO<sub>3</sub> reacts with NO<sub>2</sub> during nighttime hours to create N<sub>2</sub>O<sub>5</sub>. Daytime NO<sub>3</sub> concentrations are shown due to its relation with HNO<sub>3</sub> levels, and since they can provide an idea of the similarity of the photolysis rates included in the mechanisms. The majority of HNO<sub>3</sub> produced in all simulations during daylight hours is through the OH + NO<sub>2</sub>  $\rightarrow$  HNO<sub>3</sub> reaction, which is one of the most important daytime reactions affecting O<sub>3</sub> and HO<sub>x</sub>. During nighttime, N<sub>2</sub>O<sub>5</sub> reacts with water vapor to yield HNO<sub>3</sub>. As shown in Figure 3.3, NO<sub>3</sub> concentrations vary over a large range, and carry high relative deviations with respect to the average. Models result range from the ones predicted by CACM (average overprediction of 42% in NO<sub>3</sub> values) to the values given by RADM2 (relative deviation of 52% under the average values).

**Figure 3.3.** Simulation results for NO<sub>3</sub> (up) and HNO<sub>3</sub> concentrations (bottom) in ppb and relative deviations respect to the average behavior (%) during daylight hours. Simulation was initiated at 0h LST with the parameters and initial conditions specified in Table 3.2.

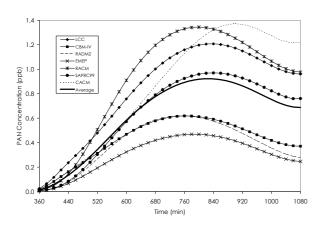

The reason behind such dramatic differences is that the mechanisms implement different NO<sub>3</sub> reactions (Table 3.3). The gas-phase reaction of NO<sub>3</sub> with water vapor has a minor importance respect to the heterogeneous reaction of NO<sub>3</sub> with liquid water, and an accurate parameterization for the rate of the heterogeneous reaction is not available. RACM and SAPRC99 include the NO<sub>3</sub> self-reaction, which is not included on the others mechanisms. CBM-IV is the most average-representative model, showing a small deviation respect to the mean values (maximum relative deviation of 12% and an average deviation of 7%). Considering nitric acid, there are high uncertainties in the kinetics of the reactions of N<sub>2</sub>O<sub>5</sub> with H<sub>2</sub>O to form HNO<sub>3</sub>. That is why some models (CB-IV, EMEP and RACM) do not include this reaction, presenting a medium-range behavior respect to HNO<sub>3</sub> (average deviations of 35%, 21% and 40%). The highest deviation from the average is that produced by the LCC, with maximum deviations of 128% and a mean deviation of 61% over the average. On the other extreme, RADM2 underpredicts average values by as much as 50%.

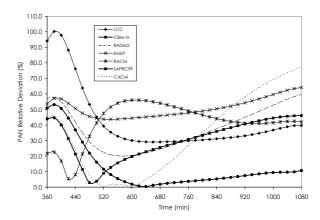

Dynamics of  $HNO_3$  are related to those of  $HO_x$ , since the reaction of nitrate with hydroperoxyl radical is one of the main sources of  $HNO_3$  in the troposphere, and rate constant differences have important effects on model predictions. The reaction of  $NO_3$  with  $H_2O_2$  to yield  $HO_2$  and nitric acid is included in all mechanisms, but with significant differences in parameterizations that lead to the diverse results presented in the simulations.

Differences shown in Figure 3.3 for the diverse models are more relevant in the latest hours of the simulation. Nevertheless, production of  $HNO_3$  in the early hours of the simulations is consistent among the mechanisms studied. Production of  $HNO_3$  during the night hours through  $N_2O_5$  reactions is implemented in different ways in the mechanisms. These differences affect not only nitric acid concentrations, but also other products such as PAN, since reactions of  $NO_3$  with carbonyls produce acyl peroxy radicals.

## 3.5.3 Peroxyacetyl Nitrate

Peroxyacetyl nitrate (PAN) has long been known to be an important atmospheric species. It acts as a reservoir for  $NO_x$  and acetyl peroxy radicals ( $C_2O_3$ ) (Stockwell *et al.*, 1995). PAN and analogues are formed during degradation of aldehydes, by the reaction of alkyl and acyl peroxy radicals with  $NO_2$ . The thermal decomposition of PAN leads to the formation of  $CO_2$ ,  $NO_2$  and peroxy radicals. In turn, the reactions of peroxy radicals lead to production of  $HO_2$  and formaldehyde, which contribute to photochemical reactions including ozone formation. Therefore, variations of PAN are related to those of ozone with respect to time of the day, but not with respect to amplitude (Grosjean *et al.*, 2001). Results obtained from this study show that peak concentrations of PAN precede those of ozone by one hour, as depicted in Figures 3.2 and 3.4.

**Figure 3.4.** Simulation results for total PAN concentrations (ppb) and relative deviations respect to the average behavior (%) during daylight hours. Simulation was initiated at 0h LST with the parameters and initial conditions specified in Table 3.2.

Peroxy nitrate species are treated differently in the mechanisms under study (Table 3.4). For instance, CACM considers 10 different peroxy nitrates depending on the source of the species. EMEP distinguishes between PAN and a peroxy methacroleinyl nitrate. Meanwhile, LCC and CBM-IV consider just the peroxyacetyl nitrate. SAPRC99 considers also peroxy propionyl nitrate and other higher alkyl PAN analogues, PAN analogues formed from aromatic aldehydes and a PAN analogue formed from methacrolein. RADM2 and RACM lump peroxy nitrates into peroxyacetyl nitrate and higher saturated PANs, and unsaturated PANs.

**Table 3.4.** Peroxy nitrate species included in the mechanisms.

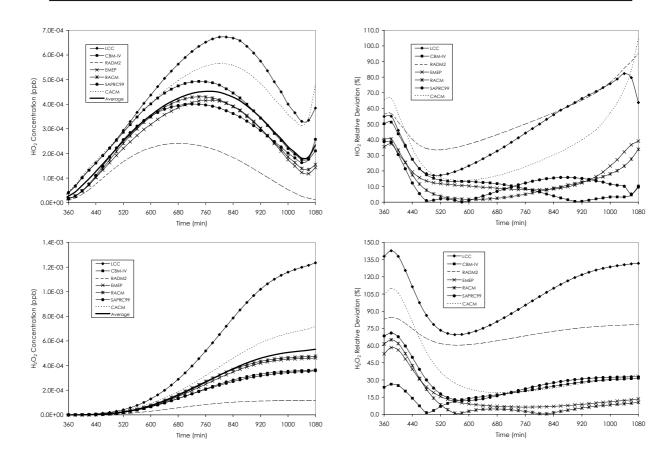

Peroxy Nitrate Species								
Reaction		CBM-IV	RADM2	EMEP	RACM	SAPRC99	CACM	
Peroxy pentionyl nitrate							Χ	
Peroxyacetyl nitrate (PAN)	Χ	Χ	Χ	Χ	Χ	Χ	Χ	
Unsaturated PANs			Χ		Χ			
Peroxy propionyl nitrate (PPN)	Χ					Χ	Χ	
Keto-PPN							Χ	
Methylene-PPN (derived from methacrolein)				Χ		Χ	Χ	
Peroxy nitrate derived from glyoxal							Χ	
Peroxy 3-methyl-heptionyl nitrate							Χ	
Peroxy 2-hydroxy-3-isopropyl-6-keto-heptionyl nitrate							Χ	
Peroxy 3-isopropyl-4-hydroxy-2-butenionyl-nitrate						V	V	
(PAN analogue derived from aromatic aldehydes)						^	^	
Peroxy nitrate derived from glyoxalic acid							Χ	

Simulations results, shown in Figure 3.4, illustrate that the amount of total PAN species formed by the various chemical schemes differs considerably. RADM2 present the lowest PAN values, with a maximum deviation respect to mean mechanisms' value around 60%. On the other side, RACM and CACM yield the highest PAN levels, with a maximum deviation of 53 and 78%, respectively. The most representative mechanism with respect to average predictions is SAPRC99, with a mean relative deviation of 12%. Peroxy nitrate formation and decay rates differ substantially

among the mechanisms, and depend on the magnitude of the competing reactions of C<sub>2</sub>O<sub>3</sub> radical, which differs in their implementation in the different mechanisms. The yield of PAN is affected strongly by the choice of rate parameters (Kley et al., 1999). While the rate of PAN formation is similar among the mechanism considered, there are various differences in the implementation of PAN decomposition. For example, in most mechanisms (CBM-IV, RADM2, RACM, SAPRC99, CACM), PAN yields the corresponding acyl peroxy radical and NO<sub>2</sub> through an equilibrium reaction, but chemical kinetics differ considerably. EMEP treats the formation of PAN as a fixed-rate reaction. On the other hand, LCC and EMEP include PAN decomposition as a strong temperature-dependent reaction, considering similar kinetics parameters. Luecken et al. (1999) reported that reactions of NO<sub>3</sub> with carbonyls, mainly acetaldehyde, lead to peroxy radicals, which react with NO<sub>2</sub> to yield peroxynitrates. Therefore, not only NO<sub>3</sub> but also aldehyde considerations in the mechanisms influence PAN concentrations. CACM and LCC use similar kinetics for the reaction of aldehydes with NO<sub>3</sub>, and this reaction rate is the highest for all the mechanisms compared, which explains the highest levels of PAN production shown in Figure 3.4 (average overpredictions of 42% and 33%, respectively). In contrast, CBM-IV and EMEP use the slowest rates. As a result, PAN concentrations are also the lowest, underestimating the average values by 30% and 51%. RADM2, RACM and SAPRC99 present similar kinetic considerations, but show different behaviors due to differences in aldehydes concentrations reported by the models. RADM2 yields the lowest aldehyde concentrations, which reflects in a lower PAN concentrations respect to the other two models with similar reaction rates.

## 3.5.4 Hydrogen Peroxide and Hydroperoxide Radical

Hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) and hydroperoxide radical (HO<sub>2</sub>) are photochemical products that serve as precursors of odd-oxygen as well as reservoirs of odd-hydrogen radicals. The generation of H<sub>2</sub>O<sub>2</sub> and HO<sub>2</sub> is affected by the levels of chemical components such as NO<sub>x</sub>, CO, methane and non-methane hydrocarbons (Lee et al., 2000). H<sub>2</sub>O<sub>2</sub> and organic peroxides chemistry is a weak point in most mechanisms, because of the many complex reactions and possible unknowns that are important under low NO<sub>x</sub>/VOCs ratio conditions (Kuhn et al., 1998). All mechanisms implement similar reactions for hydrogen peroxide: the bimolecular combination of HO<sub>2</sub>, H<sub>2</sub>O<sub>2</sub> photolysis and the reaction of H<sub>2</sub>O<sub>2</sub> with OH to regenerate HO<sub>2</sub> radicals (Table 3.3). Furthermore, kinetic constants and reaction rates are similar for all mechanisms. HO<sub>2</sub> selfreaction is the only important gas-phase source of hydrogen peroxide in the troposphere. As a result, HO<sub>2</sub> and H<sub>2</sub>O<sub>2</sub> concentrations are closely related. Rates for this reaction are identical in CACM and SAPRC99; RADM2, EMEP and RACM use the expression referenced in DeMore et al. (2000); LCC and CBM-IV differ from the rest in kinetics considerations. Figure 3.5 shows that differences among the mechanisms are important. RADM2 predicts the lowest concentrations of HO<sub>2</sub> and H<sub>2</sub>O<sub>2</sub>, with production rates that are 53% and 71% lower than the mean, and showing maximum relative deviations of 95% and 85% respectively.

**Figure 3.5.** Simulation results for  $HO_2$  (up) and  $H_2O_2$  (bottom) concentrations in ppb and relative deviations respect to the average behavior (%) during daylight hours. Simulation was initiated at 0h LST with the parameters and initial conditions specified in Table 3.2.

These deviations are due to the explicit treatment of  $HO_2$  and organic peroxide radicals in the model (Stockwell, 1995). On the other hand, LCC parameterizations lead to the highest peroxide values, producing average deviations of 46% for  $HO_2$  and 92% for  $H_2O_2$ . The mechanism that predicts concentrations closest to the average is SAPRC99 for  $HO_2$  (underestimation of 11%) and RACM for  $H_2O_2$  (underestimation of 13%).

Differences among all mechanisms originate from different considerations of water vapor dynamics. HO<sub>2</sub> and OH concentrations are overpredicted by the HO<sub>2</sub> and HO<sub>2</sub> reaction when water vapor is not considered, which leads to an underestimate of gas phase hydrogen peroxide formation rates and to an overestimate of ozone and organic peroxide formation rates (Stockwell, 1995).

#### 3.5.5 Alkenes

In the troposphere, alkenes react with atomic oxygen, OH radicals, NO<sub>3</sub> radicals and ozone through the double bonded carbons (Atkinson, 2000). The reasons for focusing on ethene and

isoprene in this study are diverse. Both are significant contributors to PAN and organic nitrate formation (Luecken *et al.*, 1999). Ethene is the simplest alkene emitted from anthropogenic sources, and because of its high reactivity with respect to ozone formation, it is included explicitly in all mechanisms. Isoprene is the most significant biogenic compound, and its chemistry is analogous to that of alkenes.

Chemicals schemes in this work aggregate biogenic stable species attending to different criteria (Table 3.5). CACM classifies biogenics attending to the potential to generate secondary organic aerosols, meanwhile most mechanisms include only isoprene, and LCC and RACM treat species explicitly as pinene, limonene, myrcene and carene. Isoprene is considered in all mechanisms because of its importance in photochemical chemistry.

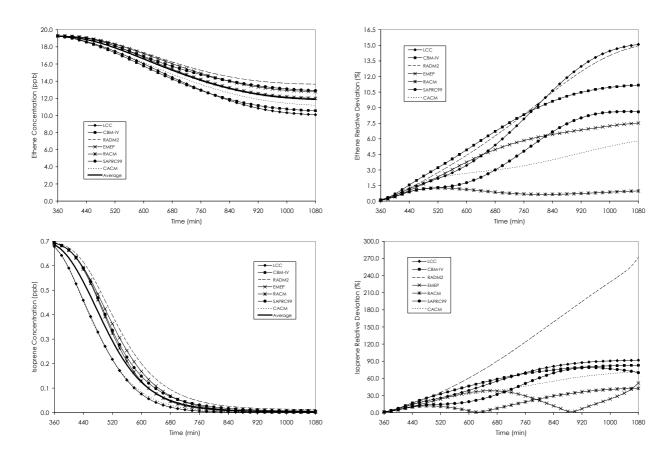

**Table 3.5.** Reactions of biogenic stable species included in the mechanisms.

Biogenic Stable Species Chemistry									
Reaction	LCC	CBM-IV	RADM2	EMEP	RACM	SAPRC99	CACM		
Isoprene + OH	Χ	Χ	Χ	Х	Х	Χ	Х		
Isoprene + NO <sub>3</sub>	Χ	Χ	Χ	Χ	Χ	Χ	Χ		
Isoprene + O <sub>3</sub>	Χ	Χ	Χ	Χ	Χ	Χ	Χ		
Isoprene + O	Χ	Χ			Χ	Χ	Χ		
APIN <sup>1</sup> + OH	Χ				Χ				
APIN + NO <sub>3</sub>	Χ				Χ				
APIN + O <sub>3</sub>	Χ				Χ				
BPIN <sup>2</sup> + OH	Χ								
BPIN + NO <sub>3</sub>	Χ								
BPIN + O <sub>3</sub>	Χ								
LIM <sup>3</sup> + OH	Χ				Χ				
LIM + NO <sub>3</sub>	Χ				Χ				
LIM + O <sub>3</sub>	Χ				Χ				
Myrcene + OH	Χ								
Myrcene + NO <sub>3</sub>	Χ								
Myrcene + O <sub>3</sub>	Χ								
γ-Carene + OH	Χ								
γ-Carene + NO₃	Χ								
γ-Carene + O <sub>3</sub>	Χ								
BIOL4 + OH							Χ		
BIOL + NO <sub>3</sub>							Χ		
BIOL + O <sub>3</sub>							Χ		
BIOL + O							X		
BIOH⁵ + OH							Χ		
BIOH + NO <sub>3</sub>							X		
BIOH + O <sub>3</sub>							Χ		
BIOH + O							Χ		

<sup>1</sup>α-pinene and other cyclic terpenes with one double bond; <sup>2</sup>β-pinene; <sup>3</sup>d-limonene and other cyclic diene-terpenes; <sup>4</sup>low SOA monoterpene species (α-terpineol); <sup>5</sup>high SOA monoterpene species (γ-terpinene)

As shown on Figure 3.6, ethene parameterization is similar in all mechanisms. The oldest mechanisms (LCC, RADM2 and CBM-IV) produce higher relative deviations, which are no larger than 16%. The kinetics of ethene are slower for RADM2, meanwhile LCC is the most-rapidly

reactive mechanism. EMEP and SAPRC99 implement similar parameterizations. Minimum deviations are under 2% for RACM, which would be the average-representative model. Isoprene is highly reactive in the atmosphere, and its lifetime is relatively short when compared to other organic species as ethene. Mechanisms that do not include atomic oxygen reaction with isoprene (RADM2 and EMEP) yield the highest overpredictions (115% and 22% respect to the average). LCC and CACM levels are under the average values (57% and 43%). Finally, RACM yields the smallest deviations respect to the mean, around 20%. One of the sources of the alkenes discrepancy among mechanisms is the alkene reaction with O $^3$ P, since RADM2 and EMEP do not include it in their schemes. Its importance derives from the fact that the kinetic constant of the alkene + O $^3$ P is of the same order of magnitude as the alkene + OH and greater than the alkene + O $^3$ 8 kinetic constant.

**Figure 3.6.** Simulation results for ethene (up) and isoprene (bottom) concentrations in ppb and relative deviations respect to the average behavior (%) during daylight hours. Simulation was initiated at 0h LST with the parameters and initial conditions specified in Table 3.2.

## 3.6 Summary and Conclusions

A comparison of photochemical mechanisms for air quality modeling is presented. Predictions of different tropospheric reaction mechanisms for a common set of initial and boundary conditions are compared to identify factors affecting the accuracy of reactivity simulations. The range of

concentrations predicted by the box mechanisms show the state-of-the-science in tropospheric chemistry. All the chemical schemes are used as part of chemical transport models, and the main conclusion of the results are summarized as follows:

- (1) NO<sub>x</sub> does not show important differences, except in the case of RADM2, since all the mechanisms relied on the same kinetic and mechanistic data for inorganic chemistry. EMEP mechanism does not include the HONO chemistry. RADM2 implements the oldest parameterizations considered in this comparison (LCC and CBM-IV are older mechanisms, but their chemistry has been revised). As a result, NO concentrations predicted by RADM2 deviate with respect to the average.
- (2) The mechanisms that tend to predict higher ozone concentrations are CACM and LCC. This high O<sub>3</sub>-productivity is accompanied by a high formation of organic hydroperoxides. Deviations in predicted ozone concentrations among the models are due to different consideration in mechanisms' compounds. This effect becomes more pronounced for reactive species producing a high yield of aldehydes, and thereby PAN and analogues.
- (3) NO<sub>3</sub> concentrations vary over a large range for the different mechanisms, and present high relative deviations with respect to the average. An explanation may come from the different NO<sub>3</sub> reactions considered in the models. HNO<sub>3</sub> tendency is also strongly related to that of HO<sub>x</sub>, since the reaction of nitrate with hydroperoxyl radical is the main source of HNO<sub>3</sub> in the troposphere. NO<sub>3</sub> + HO<sub>2</sub> is included in all mechanisms, but with important differences in parameterizations that lead to the diverse results found in the simulations.
- (4) Divergence between different mechanisms in the case of total PAN is important, since the yield of total PAN is affected by the choice of rate parameters. Peroxy nitrate formation and decay rates differ substantially among the diverse mechanisms, as well as C<sub>2</sub>O<sub>3</sub> radical reactions.
- (5) The differences in hydroperoxide and hydrogen peroxide are relevant, and are traced to the inconsistent conversion rates for HO<sub>2</sub> to H<sub>2</sub>O<sub>2</sub> reaction and to the water vapor concentration dependences of the HO<sub>2</sub> self-reaction.
- (6) Alkenes chemistry is consistent among the models considered in this comparison, and does not show important differences. Most mechanisms include similar kinetics parameterizations for ethene and isoprene, and the only important divergence comes from the fact that the reaction of these compounds with atomic oxygen is not considered in all models.

Results obtained in this work are summarized in Table 3.6. They are consistent with other comparison exercises found in the bibliography and previously exposed in section 3.2. The conclusions from this model comparison confirm that even for the simulation of extremely simple situations, there can be discrepancies in predicted concentrations. Furthermore, this study shows

that such discrepancies are significant in most of the cases and quantifies typical biases among various mechanisms.
